Dual Power MOSFET Driver

ICL7667

General Description

The ICL7667 is a dual monolithic power MOSFET driver designed to translate TTL inputs to high voltage/current outputs. Its low delay and transition times make it ideal to drive power MOSFETs for switching power supplies, motor controllers, and DC-DC converters. The ICL7667's CMOS output stage drives within millivolts of the supply rail, allowing the power MOSFETs their minimum ON resistance. The ICL7667's high speed minimizes power losses in switching power supplies and DC-DC converters due to rapid charging/discharging of the gate capacitance of the power MOSFETs. The ICL7667 inputs are TTL compatible, enabling direct interface to common switched mode power supply controllers.

Typical Operating Characteristics

ICL7667

Introduction

The ICL7667 is a dual inverting power MOSFET driver. Its delay times are nearly independent of V_{DD} . The high current output inverters can rapidly charge and discharge the gate capacitance of even the largest power MOSFETs. Since the ICL7667's inputs are CMOS, very little current is required to interface to the ICL7667. Although the ICL7667 has an input that is easy to drive, the input must never be allowed to stay between V_{IH} and V_{IL} for more than 50ns.

Other potential applications include charge pump voltage inverters and charge pump voltage multipliers.

Circuit Description

The input stage of the ICL7667 consists of a large N channel transistor with a 2mA current source as a pull-up device. The second stage inverter has a feedback device to provide some hysteresis for cleaner input switching. The output stage is a very large inverter with separate gate drives to minimize crowbar current through the supplies. The simplicity of the circuit allows for very fast delay and switching times. Unused inputs should always be connected to ground to minimize supply current. Paralleling outputs can be done by tying both inputs together and tying both outputs together.

Supply Bypassing and Grounding

Supply bypassing and grounding are extremely important with the ICL7667 product as the peak currents (both supply and output) are >1 amp. Ground drops are a form of negative feedback with inverters and will degrade the delay and transition time of the ICL7667. The suggested bypass capacitors are a 4.7μF (low ESR) capacitor in parallel with a 0.1μF ceramic capacitor. These should be mounted as close as possible to the ICL7667. Use a ground plane if possible, or use separate ground returns for the inputs and outputs.

Output Ringing

Ringing is a common problem with large dV/dt and/or large AC currents. Some preventative suggestions are:

- 1.) Use a small resistor 5-20Ω in series with the output. (This will unfortunately degrade the output transition times);
- 2.) Reduce the inductance of the ground by using a ground plane;
- 3.) Use lower ESR capacitors to bypass the ICL7667.

Power Dissipation

The power dissipation of the ICL7667 consists of three parts:

- 1.) Input inverter losses;
- 2.) Crowbar current through the output devices;
- 3.) Output current (either capacitive or resistive).

The sum of these is the total power dissipation and must be kept below the maximum power dissipation listed for the package.

The Input inverter losses come from the DC current in the input inverter. This current is 0.4mA when both inputs are low and 4mA when both inputs are high.

The Crowbar current through the output devices is the current "glitch" when the output is making a transition. This current is large (approximately 100mA) but lasts for only a few nanoseconds. It generally is a small portion of the total supply current unless the switching frequency is high and the capacitive load is very small (<100pF).

The Output current can be resistive current (example, driving an LED) or capacitive current (example, driving the gate of a power MOSFET). The ICL7667 power when driving a ground referenced resistive load is:

$$P = D \times R_{ON(MAX)} \times I_{LOAD}^2$$

where D is the percentage of time the ICL7667 output pulls high, $R_{ON(MAX)}$ is the maximum on resistance of the ICL7667 with $V_{IN} = V_{IH}$, and I_{LOAD} is the load current flowing into the ICL7667.

If the output load is capacitive, then the power is:

$$P = C_{LOAD} \times V_{DD}^2 \times FREQ$$

where C_{LOAD} is the capacitive load, V_{DD} is the ICL7667 supply, and FREQ is the toggle frequency.
